Supporting Information

ABSTRACT: We report an investigation of the adsorption of thiol and isocyanide molecules on colloidal Ag nanocubes through surface-enhanced Raman scattering (SERS). Specifically, we collect SERS spectra in situ at different time points from a mixture of Ag nanocubes and ligand molecules at a specific concentration. We demonstrate that 4-nitrothiophenol could readily bind to the Ag surface through strong thiol–Ag interaction. We also observe red shifts for the SERS peaks as the concentration decreases, suggesting a change to the molecular orientation relative to the surface. Likewise, 4-aminothiophenol also adsorbs onto Ag quickly, but gives much weaker SERS signals relative to 4-nitrothiophenol because the electron-donating amine group would retard the chemical enhancement of SERS. Different from thiols, 1,4-phenylene diisocyanide binds to Ag surface through a relatively weak, σ-donation bond. With an increase in concentration, molecules tend to adsorb on the nanocubes with the benzene ring tilting away from the surface. We further investigate the competitive binding of thiol and isocyanide, demonstrating the capability of thiol to inhibit the adsorption of isocyanide when these two ligands are presented in a mixture.

INTRODUCTION

The surface of metal nanoparticles is prone to the adsorption of organic molecules because the adsorbates can reduce the interfacial energy between the metal and its surrounding medium. If the organic molecules have a functional group with strong affinity toward the metal atom, they tend to spontaneously arrange themselves into a self-assembled monolayer (SAM), presenting a robust method for engineering the interfacial properties. Although there are extensive reports on the formation of thiol-based SAMs on Au nanoparticles, it remains challenging to characterize the surface adsorption process in gathering information such as coverage density, conformation of the adsorbed ligands, and the relative binding strengths of different ligands. To this end, it is of importance to develop a technique capable of probing the adsorption of organic molecules on the surface of nanoparticles in situ. Such a technique would also find immediate use in areas such as surface science and heterogeneous catalysis.

There are a number of documented techniques for characterizing the adsorption of organic molecules on a solid surface. As a direct method, scanning tunneling microscopy (STM) has been used extensively to visualize the SAM on a metal thin film by obtaining topological information with resolution down to the molecular level. Recent reports suggested that STM could analyze mixed-ligand SAMs on Au nanoparticles with sufficient sensitivity to distinguish between the regions comprised of different types of thiol molecules. Unfortunately, STM measurements demand a high-vacuum environment, making it impractical to gather information from a solution-phase system. Additionally, it is difficult to extract configuration of organic molecules on a solid surface from the STM data. In comparison, other indirect methods can reveal the structural details of the adsorbed molecules by leveraging molecular vibrations. Among them, Fourier-transform infrared spectroscopy (FTIR) is well-known for its ability to reveal the molecular fingerprints about the adsorbates. For example, Murray et al. demonstrated the use of FTIR to evaluate the conformations of alkanethiol molecules adsorbed on Au nanoparticles as a function of particle size and under different conditions (e.g., solid state vs solution phase). They discovered that alkanethiols would show less ordered packing on smaller particles or for the nanoparticles dispersed in nonpolar solvents. On the basis of the nonlinear optical responses from the surface of nanoparticles, second-harmonic generation (SHG) spectroscopy serves as a sensitive technique to create the adsorption isotherm, to determine the adsorption energy and coverage density, and to...
investigate the exchange of different ligands on the surface of Au nanoparticles. However, SHG inherits a number of intrinsic problems, including bulk-phase interference, sensitivity restriction, limited range of wavenumbers, and an inability to detect vibrational modes parallel to the interfacial plane as a result of surface-selection rules.

Surface-enhanced Raman scattering (SERS) offers a powerful tool for analyzing molecular adsorption on the surface of a plasmonically active metal such as Au or Ag in liquid phase and under ambient conditions. SERS shares several attributes with electron energy loss spectroscopy (EELS), including the excellent sensitivity toward low wavenumbers and the ability to detect most adsorbate through their vibrational modes. In the 1990s, Weaver and others used SERS to study the interface to detect most adsorbate through their vibrational modes. In excellent sensitivity toward low wavenumbers and the ability electron energy loss spectroscopy (EELS), including the plasmonically active metal such as Au or Ag in liquid phase and the tool for analyzing molecular adsorption on the surface of a electrode potential.23

ligand onto the surface of metal nanocrystals in a solution phase.33 Despite these prior reports, SERS has not been fully implemented to probe chemical reactions in situ on nanostructures.24,25 In recent years, SERS has been implemented to probe chemical reactions in situ on nanoparticles consisting of a plasmonic metal such as Au or Ag and a catalytic metal such a Pd or Pt. Most recently, we further demonstrated the utility of SERS in probing the heterogeneous nucleation and growth of Pd or Pt on Ag nanocubes in solution with the introduction of an isocyanide probe.31,32 Despite these prior reports, SERS has not been fully explored for in situ monitoring of the adsorption of an organic ligand onto the surface of metal nanocrystals in a solution phase.

Herein, we demonstrate the use of SERS as a platform technique to investigate the competitive adsorption of thiol and isocyanide molecules on the surface of Ag nanocubes. As illustrated in Figure 1, we selected three different ligands, 4-nitrothiophenol (4-NTP), 4-aminothiophenol (4-ATP), and 1,4-phenylene disiocyanide (1,4-PDI), to investigate their competitive adsorption on Ag and isocyanide molecules (1,4-PDI) on the surface of Ag nanocubes. This phenomenon was altered. More interestingly, we further evaluate competitive adsorption of thiol and isocyanide by dispersing Ag nanocubes in an ethanol solution containing both thiol (4-NTP or 4-ATP) and 1,4-PDI. Our results confirm the preference of thiol over isocyanide in adsorbing onto Ag surface when these two ligands are presented in comparable concentrations.

![Figure 1](image-url) Molecular structures of the ligands and schematic illustrations showing how these ligand molecules bind to the surface of Ag nanocubes.

Figure 1. Molecular structures of the ligands and schematic illustrations showing how these ligand molecules bind to the surface of Ag nanocubes.

Different from thiol molecules whose vibrational modes exhibit essentially no dependence on the metal surface, the binding of the isocyanide group (−NC) to a transition metal is similar to that of carbon monoxide, making the stretching frequency of the NC bond (ν_{NC}) sensitive to the interaction between the −NC group and the metal.42−45 The carbon is assumed to bind to Ag through σ-donation, by which the lone-pair electrons are donated from the antibonding σ* orbital of the −NC group to the d-band of Ag. It is anticipated that there are two possible configurations of 1,4-PDI on the surface of Ag nanocubes. The first configuration involves the binding of one −NC group to Ag in a standing geometry with respect to the surface while leaving the other −NC group free.40 The second one reflects the binding of both −NC groups to the Ag surface.

In this work, we investigate the adsorption of 4-NTP, 4-ATP, and 1,4-PDI on the surface of colloidal Ag nanocubes suspended in ethanol by in situ SERS. In a typical process, we disperse the acid-treated Ag nanocubes in an ethanol solution containing either 4-NTP, 4-ATP, or 1,4-PDI, followed by the collection of SERS spectra at different time points. Because the SERS hot spots are located on the edges of Ag nanocubes, we actually monitored the adsorption of thiol or isocyanide on the edges. By varying the concentration of each solution, there are some subtle differences in the vibrational peaks from the SERS spectra, suggesting that the configurations of molecules on the Ag surface likely change when the surface coverage of ligand molecules was altered. More interestingly, we further evaluate competitive adsorption of thiol and isocyanide by dispersing Ag nanocubes in an ethanol solution containing both thiol (4-NTP or 4-ATP) and 1,4-PDI. Our results confirm the preference of thiol over isocyanide in adsorbing onto Ag surface when these two ligands are presented in comparable concentrations.

### EXPERIMENTAL SECTION

**Chemicals.** Ethylene glycol (EG) was purchased from J. T. Baker (Avantor Performance Materials, LLC, Center Valley, PA). Silver trifluoroacetate (CF₃COOAgov 99.99%), sodium hydrosulfide hydrate (NaHS·xH₂O), poly(vinylpyrrolidone) (PVP) with an average molecular weight of 29 000 (PVP-29), aqueous hydrochloric acid (HCl, 37 wt %), L-ascorbic acid (H₂Asc, 99%), ethyl alcohol (ethanol, ≥ 99.5%), 1,4-phenylene diisocyanide (1,4-PDI, 97%), 4-nitrothiophenol (4-NTP, 80%), and 4-aminothiophenol (4-ATP, 97%) were ordered from Sigma-Aldrich (St. Louis, MO). Acetone (≥ 99.5%) was purchased from Alfa Aesar (Haverhill, MA). All chemicals were used as received. Deionized (DI) water with a resistivity of 18.2 MΩ·cm at room temperature was obtained from the EMD Millipore Direct-Q 3UV ultrapure water purification system (MilliporeSigma, Burlington, MA).

**Synthesis of Ag Nanocubes.** We followed a published protocol involving polyol reduction to synthesize the Ag
The as-prepared Ag nanocubes were washed once with acetone, followed by three times with water, and then dispersed in water for storage and future use. The stock suspension of Ag nanocubes contained \(1.2 \times 10^{13}\) particles per mL.

**Acid Treatment of Ag Nanocubes.** In a standard protocol, we mixed 0.5 mL of aqueous H\(_2\)Asc (0.1 M) and 2 mL of aqueous PVP-29k (1 mM) in 0.5 mL of water in a 23 mL glass vial under magnetic stirring at 650 rpm. Next, we injected 25 \(\mu\)L of Ag nanocubes to the acidic solution to attain approximately \(3.0 \times 10^{11}\) particles. The mixture was magnetically stirred under ambient conditions for 2 h. Afterward, the solution was divided and transferred into three centrifuge tubes, followed by their centrifugation at 5500 rpm for 15 min. After the removal of the supernatant, the solids were used without further modification for the SERS experiments. For TEM characterization, the solids were washed with ethanol twice and drop-casted onto a TEM grid.

**Monitoring the Adsorption of 4-NTP, 4-ATP, or 1,4-PDI on Ag Nanocubes by SERS.** In a standard protocol, we first recorded a Raman spectrum from the ligand, such as 4-NTP, 4-ATP, or 1,4-PDI in ethanol solution at the concentration of \(10^{-5}\) M, as a reference. Next, we mixed the ligand solution with the Ag nanocubes, followed by rigorous shaking to disperse the nanocubes. Finally, we withdrew aliquots from each sample at 3, 15, 30, 45, 60 min for SERS measurements. For the experiments involving different concentrations of ligand, we followed the standard protocol except that the ligand solution was changed to either \(10^{-4}\) or \(10^{-7}\) M.

**Monitoring the Competitive Adsorption of 1,4-PDI and 4-NTP, as well as 1,4-PDI and 4-ATP, on Ag Nanocubes by SERS.** In a typical experiment, we mixed two ligand solutions (4-NTP and 1,4-PDI or 4-ATP and 1,4-PDI), each at a doubled concentration (that is, \(2 \times 10^{-5}\), \(2 \times 10^{-5}\), or \(2 \times 10^{-7}\) M) relative to the standard protocol, in equal volumes. As a result, the final mixture would preserve the concentrations of each ligand relative to the single-ligand experiments. We then followed the standard protocol except that the mixture was used as the ligand solution.

**Raman Measurements.** We performed our Raman measurements using a Renishaw inVia Raman spectrometer (Wotton-under-Edge, U.K.) coupled with a Leica optical microscope (Leica Camera, Wetzlar, Germany). In a typical measurement, we transferred an aliquot of 20 \(\mu\)L from the sample into a transparent polydimethylsiloxane (PDMS) cell, covered the cell with a thin cover glass, and placed the cell on the sample stage of microscope. After we used the static mode for collecting consecutive Raman spectra every second to confirm that the Raman signal was relatively stable (variation is within 100 counts), we recorded the Raman spectrum on the extended mode, using the excitation wavelength of 532 nm, 100X objective, 10% of the laser power (maximum power of 50 mW), and 10 s collection time.

**Quantitative Analysis of Raman Data.** We used Renishaw’s WiRE 5.1 software to capture the area under the peaks of the characteristic Raman bands present in the SERS spectra at each time point in the experiment, specifically the \(\nu_{CC}\) band of 4-NTP and the \(\nu_{NC(Ag)}\) band of 1,4-PDI. For each data point, we performed the analysis according to the following procedure. In the first step, we loaded the raw data into the software and then centered the viewing window around the peak of interest (1520–1620 cm\(^{-1}\) for the \(\nu_{CC}\) band, and 2000–2300 cm\(^{-1}\) for the \(\nu_{NC}\) band). In the second step, based on the curve-fitting function in the software, we attempted to fit the data using a single Gaussian—Lorentzian peak (50% of each character). The software optimized the curve fit model to minimize the sum of the squared deviations of the fitting from the experimental data, updating the information such as the peak center, peak width, peak height, and the shape (proportion of the Gaussian character). If we could not fit the band, we would add a second peak and perform the optimization again to better capture the peak area of this band. Finally, we took the sum of the peak areas of all curves used in this fitting to obtain the total area under the peak.

**RESULTS AND DISCUSSION**

We prepared Ag nanocubes by following the protocol published by Xia and co-workers.\(^4\) To remove any oxides on the surface, we dispersed the Ag nanocubes in an acidic solution (pH = 3.1) containing H\(_2\)Asc and PVP under magnetic stirring for 120 min. Figure S1 shows TEM images of the samples before and after acid treatment, indicating no significant changes to the morphology of nanocubes. After collecting the acid-treated Ag nanocubes via centrifugation, we immediately redispersed them in an ethanol solution containing the ligand molecules, followed by withdrawing aliquots from each sample at various time points for SERS measurements. In this study, we assume that the primary contribution to SERS signals would come from molecules adsorbed on the edges of individual Ag nanocubes where hot spots are located, rather than from those situated in the interparticle junctions.\(^3\) To validate our hypothesis, we recorded UV–vis spectra from the Ag nanocubes dispersed in the acid solution and the acid-treated nanocubes redispersed in the ethanol solution. As shown in Figure S2, there was essentially no change to the UV–vis spectra, confirming the absence of aggregation for the acid-treated Ag nanocubes redispersed in the ethanol solution. It is also worth mentioning that we could use the Raman peak of ethanol at 879 cm\(^{-1}\) as an internal reference to calibrate the Raman system. As confirmed by the spectra in Figure S3, this band remained at essentially the same position before and after the introduction of Ag nanocubes.

We initially studied the interaction of thiols with Ag nanocubes by employing 4-NTP as the ligand. Figure 2A shows Raman spectra collected from a 4-NTP solution (10\(^{-5}\) M) in ethanol before and after adding the acid-treated Ag nanocubes. On the basis of our back-of-the-envelope calculation, it is reasonable to assume that the 4-NTP molecules at this concentration would be able to form a full coverage on the Ag nanocubes. In the absence of Ag nanocubes, the Raman spectrum only shows the peaks associated with ethanol. At \(t = 3\) min after the introduction of nanocubes, the characteristic peaks of 4-NTP appeared at 1083 (C=S stretching, \(\nu_{CS}\)), 1336, 1347 (NO\(_2\) stretching,
νNO₂), and 1572 cm⁻¹ (C–C stretching, νCC). The frequencies and intensities of these peaks did not change over a period up to t = 60 min. It is worth mentioning that we calibrated our Raman spectrometer using Si(100) as a reference every time before we performed SERS measurements. On the basis of 20 calibrations, Table S1 shows that the spectrometer consistently gives the Raman shift of Si(100) at 520.29 cm⁻¹ with a standard deviation of 0.09 cm⁻¹. With regard to the peak intensity, Figure 2B shows the time-dependent SERS spectra (in the form of a heat map) of 4-NTP collected 3 min after the introduction of Ag nanocubes into the 4-NTP ethanol solutions at concentrations of 10⁻⁷ M and 10⁻⁴ M, respectively.

Figure 2. (A) Raman spectrum of 4-NTP ethanol solution (10⁻⁵ M) and the SERS spectra of 4-NTP collected from the same solution at different time points after the introduction of Ag nanocubes. (B) Time-dependent SERS spectra of 4-NTP collected at 3 min. (C) SERS spectra of 4-NTP collected at t = 60 min after introducing Ag nanocubes into the 4-NTP ethanol solutions at concentrations of 10⁻⁷ M and 10⁻⁴ M, respectively.

νNO₂, and 1572 cm⁻¹ (C–C stretching, νCC). The frequencies and intensities of these peaks did not change over a period up to t = 60 min. It is worth mentioning that we calibrated our Raman spectrometer using Si(100) as a reference every time before we performed SERS measurements. On the basis of 20 calibrations, Table S1 shows that the spectrometer consistently gives the Raman shift of Si(100) at 520.29 cm⁻¹ with a standard deviation of 0.09 cm⁻¹. With regard to the peak intensity, Figure 2B shows the time-dependent SERS spectra (in the form of a heat map) of 4-NTP collected 3 min after the introduction of Ag nanocubes into 10⁻⁷ M 4-NTP ethanol solution, suggesting that the SERS signal remains stable during the collection time of 10 s. It is interesting to note that the stretching mode of NO₂ (νNO₂) was split into two peaks at 1336 and 1347 cm⁻¹. Although this observation is different from those reported in previous ex situ SERS experiments involving 4-NTP,⁴¹,⁵⁰ we are still unable to fully elucidate the nature of these two peaks at the moment.

By varying the concentration of 4-NTP while keeping the number of Ag nanocubes unchanged in the ethanol solution, we investigated how the molecules would interact with the Ag surface differently. At t = 60 min, Figure 2C shows the SERS spectra of 4-NTP adsorbed onto the Ag nanocubes from solutions with concentrations at 10⁻⁷ and 10⁻⁴ M, respectively. At 10⁻⁷ M, we noticed that the Raman peaks of 4-NTP were noticeably red-shifted to 1079 (νCS), 1330 (νNO₂), and 1568 cm⁻¹ (νCC), respectively, while the other νNO₂ peak at 1346 cm⁻¹ was missing. Based on peak areas of νNO₂, the SERS signal became 20-fold weaker relative to that of 10⁻⁵ M. Conversely, at 10⁻⁴ M, the peaks of 4-NTP appeared at 1083 (νCS), 1334, 1347 (νNO₂), and 1573 cm⁻¹ (νCC), consistent with the peak positions at 10⁻⁵ M. Also, the peak intensities were comparable to those shown in Figure 2A.

To further evaluate the concentration-dependent adsorption of 4-NTP on Ag nanocubes, we performed SERS measurements three times at concentrations of 10⁻⁷, 10⁻⁵, or 10⁻⁴ M, respectively. By fitting the νCS band (see details in the Experimental Section), Figure 3 shows three plots of the peak area as a function of time at three concentrations. Our data suggest that the SERS signal reached a stable state within 3 min regardless of the concentration of 4-NTP, suggesting that the adsorption of 4-NTP on the surface of Ag nanocubes

Figure 3. Plots of peak area for the νCC band of 4-NTP as a function of time at the concentration of (A) 10⁻⁷, (B) 10⁻⁵, and (C) 10⁻⁴ M, respectively.
could reach equilibrium at a time scale less than 3 min. Because the SERS hot spots are located on the 12 edges of a Ag nanocube while the cube is predominantly enclosed by six side faces, it is not surprising to resolve much weak SERS signal at a concentration of $10^{-7}$ M when only a limited number of molecules occupied the edges of nanocubes. In comparison, when the concentration was increased to $10^{-5}$ and then to $10^{-4}$ M, the SERS signals became stronger and reached saturation, suggesting that the molecules could fully cover the edges of Ag nanocubes where the SERS hot spots were located. On the other hand, the difference in Raman shifts of 4-NTP at various concentrations may suggest that the 4-NTP molecules could adsorb on the surface of Ag nanocubes in different configurations. It has been established that the orientation of the adsorbed thiols on a metal surface is dependent on the packing density and thus the concentration of the ligand molecules. For example, alkanethiols have been reported to assume an orientation parallel to the metal surface when used at low concentrations, while taking a more or less perpendicular orientation at relatively high concentrations. From this perspective, it is possible that the red-shifted SERS peaks observed for 4-NTP at $10^{-7}$ M reflects those of parallel-lying molecules at a low packing density, whereas the peaks of 4-NTP at $10^{-5}$ or $10^{-4}$ M correspond to those perpendicular to the surface in a closely packed monolayer.

We then examined the interaction of 4-ATP with Ag nanocubes. When the electron-withdrawing nitro group is substituted by an electron-donating amine group, we would expect a change to the direction of electron flow between the Ag surface and the molecule, leading to a diminish of chemical enhancement. As anticipated, when the ligands were used at the same concentration of $10^{-5}$ M, the intensities of the 4-ATP signals were much weaker than those from 4-NTP (Figure 2A). This trend supports our argument that the signals from 4-ATP should be weaker due to the lack of chemical enhancement. As shown in Figure 2B, we could hardly resolve any peaks associated with 4-ATP at $10^{-7}$ M while the two peaks located at 1080 ($\nu_{CS}$) and 1594 cm$^{-1}$ ($\nu_{CC}$) returned at $10^{-4}$ M at the time point of 60 min.

Different from thiols that form a relatively strong Ag–S bond with the Ag surface, 1,4-PDI weakly binds to the surface of Ag nanocubes through $\sigma$-donation. Figure 3A shows the SERS data collected from the acid-treated Ag nanocubes after being redispersed in the 4-ATP ethanol solution ($10^{-5}$ M). At $t = 3$ min, the characteristic peaks of 4-ATP appeared at 1080 (C–S stretching, $\nu_{CS}$) and 1593 cm$^{-1}$ (C–C stretching, $\nu_{CC}$). These two peaks did not change their positions and intensities up to $t = 60$ min, consistent with the behavior of 4-NTP. As anticipated, when the ligands were used at the same concentration of $10^{-5}$ M, the intensities of the 4-ATP signals were much weaker than those from 4-NTP (Figure 2A). This trend supports our argument that the signals from 4-ATP should be weaker due to the lack of chemical enhancement. As shown in Figure 2B, we could hardly resolve any peaks associated with 4-ATP at $10^{-7}$ M while the two peaks located at 1080 ($\nu_{CS}$) and 1594 cm$^{-1}$ ($\nu_{CC}$) returned at $10^{-4}$ M at the time point of 60 min.

Raman spectra collected from a 1,4-PDI solution ($10^{-5}$ M) in ethanol before and after adding the acid-treated Ag nanocubes. At $t = 3$ min, the characteristic peaks of 1,4-PDI emerged at 1164 (C–H bending, $\delta_{CH}$), 1204 (C–NC stretching, $\nu_{C-NC}$), and 1597 (C–C stretching, $\nu_{CC}$), 2125 (N–C stretching, $\nu_{NC(Ag)}$) and 2177 cm$^{-1}$ (N–C stretching, $\nu_{NC(Ag)}$). At $t = 30$ min, there was a slight increase in peak intensity. The SERS spectrum then shows little change up to $t = 60$ min. It is interesting to note that the N–C stretching mode appeared at...
2177 and 2125 cm\(^{-1}\) in the SERS spectrum with their assignments to the \(\nu_{\text{NC(Ag)}}\) and \(\nu_{\text{NC(free)}}\) respectively.\(^{46}\) The presence of the \(\nu_{\text{NC(free)}}\) peak suggests that the 1,4-PDI molecules would bind to the surface of the Ag nanocubes through one of its two isocyanide groups only, with the benzene ring tilting away from the surface. We also collected SERS spectra of acid-treated Ag nanocubes after they had been incubated with 1,4-PDI solutions of 10\(^{-7}\) and 10\(^{-4}\) M, respectively, at the time point of 60 min. As shown in Figure 5B, at 10\(^{-7}\) M, the \(\nu_{\text{NC(free)}}\) peak was not identified while the \(\nu_{\text{NC(Ag)}}\) peak remained almost unchanged at 2176 cm\(^{-1}\). In comparison, at 10\(^{-4}\) M, we resolved both the \(\nu_{\text{NC(Ag)}}\) and \(\nu_{\text{NC(free)}}\) peaks. Based on the peak areas of \(\nu_{\text{NC(Ag)}}\), the overall SERS signal is about 2-fold weaker at 10\(^{-7}\) M or 4-fold stronger at 10\(^{-4}\) M compared with that of 10\(^{-5}\) M.

To confirm the orientation of 1,4-PDI on Ag surface, we monitored the \(\nu_{\text{CH}}\) band located at 3065 cm\(^{-1}\). According to the surface selection rule, this band can only be identified when the benzene ring is tilting away from the surface.\(^{33}\) Figure 6A and B). When we functionalized Ag nanocubes with 1,4-PDI of 10\(^{-7}\) M, followed by SERS detection by increasing the number of Ag nanocubes that are four times larger than those used in the standard protocol to improve detection sensitivity, Figure 6C shows no observation of the \(\nu_{\text{CH}}\) band even though the increase in the number of nanocubes for this set of SERS measurements was able to increase the peak intensity of \(\nu_{\text{NC(Ag)}}\) band significantly to the signal level comparable to that of \(\nu_{\text{NC(free)}}\) band collected from Ag nanocubes functionalized with 1,4-PDI of 10\(^{-5}\) M. Figure S4 shows the direct comparison of the \(\nu_{\text{NC(Ag)}}\) band, from which one still cannot resolve the \(\nu_{\text{NC(free)}}\) band. Altogether, we believe that a larger proportion of the 1,4-PDI molecules would bind to the edges of Ag nanocubes, the SERS hot spots, through a single isocyanide group, likely in a benzene ring tilting away from the surface, at a high concentration for accommodating closely packed configuration. In the case of 10\(^{-5}\) M, it is possible that the molecules might bind to the Ag surface through both isocyanide groups rather than only one of them at such low concentration.

Based on the results shown in Figures 2–6, we argue that 4-NTP, 4-ATP, and 1,4-PDI all can readily adsorb onto the surface of Ag nanocubes dispersed in ethanol. To further examine the difference between thiol and isocyanide, we evaluated their competitive adsorption onto the surface of Ag nanocubes by introducing the acid-treated Ag nanocubes into an ethanol solution containing both types of ligands at specific concentrations. Figure 7A shows the Raman spectra collected from an ethanol solution containing 4-NTP and 1,4-PDI (both at 10\(^{-5}\) M). At \(t = 3\) min, the peaks at 1083, 1336, 1347, and 1572 cm\(^{-1}\) could be assigned to \(\nu_{\text{CS}}, \nu_{\text{NO}}\), and \(\nu_{\text{CC}}\) of 4-NTP, respectively. However, we could not resolve well-defined peaks associated with 1,4-PDI, except an extremely weak peak located at 2172 cm\(^{-1}\). The SERS spectrum remained essentially the same up to \(t = 60\) min. These data confirm that thiol would adsorb onto Ag surface more competitively on the edges of Ag nanocubes where the hot spots are located for SERS detection. Interestingly, when we reduced the 4-NTP concentration by 100-fold to 10\(^{-7}\) M while keeping the concentration of 1,4-PDI at 10\(^{-5}\) M, at \(t = 3\) min, Figure 7B shows the appearance of peaks characteristic of 1,4-PDI at 2123 (\(\nu_{\text{NC(free)}}\)) and 2178 cm\(^{-1}\) (\(\nu_{\text{NC(Ag)}}\)), together with characteristic peaks of 4-NTP at 1080 (\(\nu_{\text{CS}}\)), 1330 (\(\nu_{\text{NO}}\)), and 1568 cm\(^{-1}\) (\(\nu_{\text{CC}}\)). We also observed increase in peak intensity for the \(\nu_{\text{NC(Ag)}}\) band of 1,4-PDI while there was essentially no change to the peaks of 4-NTP by \(t = 30\) min. From \(t = 30\) to 60 min, the SERS spectrum remained unaltered. These results infer that 4-NTP and 1,4-PDI could coexist on the edges of Ag nanocubes.

To further understand the concentration-dependent adsorption of 4-NTP and 1,4-PDI on Ag nanocubes, we repeated the SERS measurements and then analyzed the results. Fitting the \(\nu_{\text{CC}}\) band of 4-NTP, Figure 8A, shows a plot of the peak area as a function of time by benchmarking against 4-NTP (10\(^{-5}\) M). In this case, we noticed that the SERS signal was comparable to that of 4-NTP, suggesting that the 4-NTP could competitively bind to the edges of Ag nanocubes over 1,4-PDI when they were used at the same concentration. On the other hand, when we decreased the concentration of 4-NTP to 10\(^{-7}\) M while keeping the concentration of 1,4-PDI at 10\(^{-5}\) M, Figure 8B shows a plot of the \(\nu_{\text{CC}}\) band of 4-NTP as a function of time by benchmarking against the plot of 4-NTP (10\(^{-7}\) M). Under this condition, we observed an increase in the peak area.
of 4-NTP when 100-fold more 1,4-PDI molecules were involved in the solution. Because 4-NTP at $10^{-7}$ M was unable to cover the entire surface of Ag nanocubes, we suspect that the adsorption of 1,4-PDI would occur on the side faces of nanocubes, making it possible to favor the preferential adsorption of 4-NTP molecules on the edges of nanocubes for an increase in the SERS signal.

Figure 8C shows a plot of the $\nu_{CC}$ band of 1,4-PDI as a function of time when 4-NTP ($10^{-7}$ M) was mixed with 1,4-PDI ($10^{-5}$ M) by benchmarking against 1,4-PDI ($10^{-5}$ M).

3 min, we observed the peaks of 4-ATP at 1080 ($\nu_{CS}$) and 1595 ($\nu_{CC}$) but not the $\nu_{NC(free)}$ and $\nu_{NC(Ag)}$ bands of 1,4-PDI. Because the $\nu_{CC}$ bands of both 1,4-PDI and 4-ATP overlap with each other, we cannot rely on this band for the identification of 1,4-PDI. From $t = 30$ to 60 min, there was essentially no change to the SERS spectrum. These results are similar to the case of 1,4-PDI and 4-NTP, confirming that thiol binds more strongly to Ag surface than isocyanide regardless of the difference in the terminal group (NO$_2$ vs NH$_2$). Because it was difficult to resolve any SERS signal when decreasing the concentration of 4-ATP from $10^{-5}$ to $10^{-7}$ M (see Figure 4B), we increased the concentration of 1,4-PDI to $10^{-3}$ M while keeping the 4-ATP concentration at $10^{-5}$ M to attain a molar ratio of 4-ATP to 1,4-PDI molecules at 1:100. In this case, at $t = 3$ min, Figure 9B shows the characteristic peaks of 1,4-PDI at 2125 ($\nu_{NC(free)}$) and 2171 cm$^{-1}$ ($\nu_{NC(Ag)}$) in addition to the peaks of 4-ATP. These results suggest that both 4-ATP and 1,4-PDI could adsorb on the edges of Ag nanocubes at comparable rates when 1,4-PDI was in access, consistent with results of 4-NTP and 1,4-PDI.

**CONCLUSIONS**

We have explored the use of in situ SERS to investigate the adsorption of different ligands on the surface of colloidal Ag
through from the case of thiol, 1,4-PDI would bind to an Ag surface time scale of 60 min. At a concentration of 10^{-5} M, however, the 1,4-PDI signals became detectable when its concentration was increased by 100 times relative to 4-NTP or 4-ATP. Collectively, our data indicate that the thiols have a much stronger binding to the surface on Ag nanocubes, making it possible to impede or even inhibit the adsorption of isocyanides.

nanocubes. In a typical process, we collected SERS spectra at different time points from a mixture of Ag nanocubes and a ligand such as 4-NTP, 4-ATP, or 1,4-PDI at a specific concentration. Time-dependent SERS spectra of 4-NTP indicate that the adsorption could be achieved within 3 min due to the strong binding of thiol to Ag surface. We also recorded the concentration-dependent SERS spectra of 4-NTP, from which we observed a red shift for all peaks at a concentration of 10^{-7} M relative to the case of 10^{-5} or 10^{-4} M. We argue that such a red shift could be attributed to the difference in molecular orientation, with the benzene ring oriented parallel to or tilting away from the surface at low and high concentrations, respectively. We confirmed that the adsorption kinetics of 4-ATP on Ag was similar to that of 4-NTP, although the SERS signals from 4-ATP were much weaker due to the absence of chemical enhancement. Different from the case of thiol, 1,4-PDI would bind to a Ag surface through σ-donation, giving slower adsorption kinetics over a time scale of 60 min. At a concentration of 10^{-5} M and above, we observed both ν_{NC(free)} and ν_{NC(Ag)} peaks in the SERS spectra, suggesting that the 1,4-PDI molecules could be oriented with the benzene ring tilting away from the surface. We further evaluated the relative binding strength of the thiol and isocyanide groups toward Ag surface by dispersing Ag nanocubes in an ethanol solution containing both ligands. The SERS signals from 1,4-PDI were not detectable in either case when it was used at the same concentration as 4-NTP or 4-ATP at 10^{-5} M. However, the 1,4-PDI signals became detectable when its concentration was increased by 100 times relative to 4-NTP or 4-ATP. Collectively, our data indicate that the thiols have a much stronger binding to the surface on Ag nanocubes, making it possible to impede or even inhibit the adsorption of isocyanides.
